Abstract. We investigate large scale structure formation of collisionless dark matter in the phase space description based on the Vlasov-Poisson equation. We present the Schrödinger method, originally proposed by [Widrow and Kaiser, 1993](#) as numerical technique based on the Schrödinger Poisson equation, as an analytical tool which is superior to the common standard pressureless fluid model. Whereas the dust model fails and develops singularities at shell crossing the Schrödinger method encompasses multi-streaming and even virialization.

Keywords. large scale structure, cold dark matter, cosmic web, halo formation

Introduction. The standard model of large-scale structure and halo formation is based on collisionless cold dark matter (CDM), a particle species that for this purpose can be assumed to interact only gravitationally and to be cold or initially single-streaming. We are therefore interested in the dynamics of a large collection of identical point particles that via gravitational instability evolve from initially small density perturbations into eventually bound structures, like halos that are distributed along the cosmic web.

1. Phase space description of cold dark matter

The dynamics of CDM with mass m is described by the one-particle phase space density $f(\mathbf{x}, \mathbf{p}, t)$ which fulfills the Vlasov-Poisson equation

$$\partial_t f = -\frac{\mathbf{p}}{a^2 m} \cdot \nabla_{\mathbf{x}} f + m \nabla_{\mathbf{x}} V \cdot \nabla_{\mathbf{p}} f \quad , \quad \Delta V = \frac{4\pi G \rho_0}{a} \left(\int d^3 p f - 1 \right) . \quad (1.1)$$

This description is valid in the absence of irreducible two-body correlations, which is the case for a smooth matter distribution. The cosmology dependence is encoded in the scale factor a , today's background matter density ρ_0 and the initial conditions f_{ini} .

Cumulants. The cumulants $C^{(n)}$ of the phase space distribution are in practice the physical quantities of interest – observationally accessible via redshift space distortions and peculiar velocities or numerically determinable from N-body simulations. They encode the number density $n(\mathbf{x}) = \exp C^{(0)}$, the velocity $u_i(\mathbf{x}) = C_i^{(1)}$ and the velocity dispersion $\sigma_{ij} = C_{ij}^{(2)}$. They can be calculated from f as

$$G[\mathbf{J}] = \int d^3 p \exp[i\mathbf{p} \cdot \mathbf{J}] f \quad , \quad C_{i_1 \dots i_n}^{(n)} := (-i)^n \frac{\partial^n \ln G[\mathbf{J}]}{\partial J_{i_1} \dots \partial J_{i_n}} \Big|_{\mathbf{J}=0} . \quad (1.2)$$

For a general f it is impossible to perform the integration over momentum analytically. Therefore we would like to resort to an ansatz with a specific \mathbf{p} -dependence.

Vlasov hierarchy. The Vlasov hierarchy is constituted by the evolution equations for the cumulants $C^{(n)}$ determined from the Vlasov equation (1.1)

$$\partial_t C^{(n)} = -\frac{1}{a^2 m} \left\{ \nabla \cdot C^{(n+1)} + \sum_{|S|=0}^n C^{(n+1-|S|)} \cdot \nabla C^{(|S|)} \right\} - \delta_{n1} m \nabla V . \quad (1.3)$$

It is an infinite coupled hierarchy: in order to determine the time-evolution of the n -th cumulant, the $(n+1)$ -th is required. The dust model with $C^{(n \geq 2)} = 0$ is the only consistent truncation but fails after shell-crossing where all cumulants become equally important as demonstrated by [Pueblas and Scoccimarro, 2009].

Dust model. The dust model is an ansatz for the phase-space distribution function with trivial \mathbf{p} -dependence

$$f_d(\mathbf{x}, \mathbf{p}, t) = n_d(\mathbf{x}, t) \delta(\mathbf{p} - \nabla \phi_d(\mathbf{x}, t)). \quad (1.4)$$

The cumulants are given by the density $C_d^{(0)} = \ln n_d(\mathbf{x}, t)$ and a curl-free velocity $\mathbf{C}_d^{(1)} = \nabla \phi_d(\mathbf{x}, t)/m$ since all higher cumulants vanish identically $C_d^{(n \geq 2)} = 0$. Therefore solving the Vlasov equation for f_d is equivalent to solving the coupled fluid system consisting of continuity and Bernoulli equation for n_d and ϕ_d .

$$\partial_t n_d = -\frac{\nabla \cdot (n_d \nabla \phi_d)}{a^2 m}, \quad \partial_t \phi_d = -\frac{1}{2} \frac{(\nabla \phi_d)^2}{a^2 m} - m V_d, \quad \Delta V_d = \frac{4\pi G \rho_0}{a} (n_d - 1). \quad (1.5)$$

2. The Schrödinger method

The Schrödinger method (ScM), originally proposed by [Widrow and Kaiser, 1993] as numerical technique to study CDM dynamics, is a special ansatz for the distribution function that is based on the Schrödinger Poisson equation

$$i\hbar \partial_t \psi = -\frac{\hbar^2}{2a^2 m} \Delta \psi + mV(\mathbf{x})\psi, \quad \Delta V = \frac{4\pi G \rho_0}{a} (|\psi|^2 - 1). \quad (2.1)$$

If a wavefunction ψ fulfils (2.1) then the Husimi distribution function f_H

$$f_H(\mathbf{x}, \mathbf{p}, t) = N \left\{ \int d^3 y \exp \left[-\frac{(\mathbf{x} - \mathbf{y})^2}{4\sigma_x^2} - \frac{i}{\hbar} \mathbf{p} \cdot \left(\mathbf{y} - \frac{1}{2} \mathbf{x} \right) \right] \psi(\mathbf{y}, t) \right\}^2, \quad (2.2)$$

where \hbar and σ_x are free parameters and $N(\hbar, \sigma_x)$ is a normalization constant, approximately fulfils the coarse grained Vlasov equation [Takahashi, 1989] obtained by a Gaussian smoothing of f over σ_x and $\sigma_p = \hbar/(2\sigma_x)$. Therefore, physical processes taking place at scales larger than σ_x and σ_p can be modeled with arbitrary precision.

Key features. The advantages of the Schrödinger method compared to the standard dust model are summarized in Tab. 1. The special \mathbf{p} -dependence of (2.2) allows to compute cumulants analytically. All cumulants are nonzero and can be expressed as Gaussian smoothed functions of n and $\nabla \phi$ and their derivatives which allows for closing the Vlasov hierarchy, see [Uhlemann, Kopp and Haug, 2014].

	Schrödinger method $f_H(\mathbf{x}, \mathbf{p}, t)$	dust model $f_d(\mathbf{x}, \mathbf{p}, t)$
degrees of freedom	$1 \times \mathbb{C}$: $\psi = \sqrt{n} \exp[i\phi/\hbar]$	$2 \times \mathbb{R}$: n_d, ϕ_d
equations of motion	Schrödinger-Poisson equation (2.1)	fluid equations (1.5)
Vlasov equation (1.1) solved	approximately (\hbar, σ_x)	exactly
shell-crossing	well-behaved	singularities
multi-streaming, virialization	✓, ✓	✗, ✗
closed-form cumulants	✓, $C^{(n \geq 2)} \neq 0$	(✓), $C^{(n \geq 2)} \equiv 0$

Table 1. Comparison between the Schrödinger method and the dust model

Numerical example: Pancake collapse. In Fig. 1 we show the standard toy example of plane parallel (or pancake) collapse, whose exact solution in the case of dust is given by the Zel'dovich approximation [Zel'dovich, 1970]. We therefore have analytic expressions for n_d and ϕ_d . Nearly cold initial conditions can be implemented by choosing the initial wave function at some early time where shell crossings have not yet occurred as

$$\psi_{\text{ini}}(x) = \sqrt{n_d(a_{\text{ini}}, x)} \exp[i\phi_d(a_{\text{ini}}, x)/\hbar] . \quad (2.3)$$

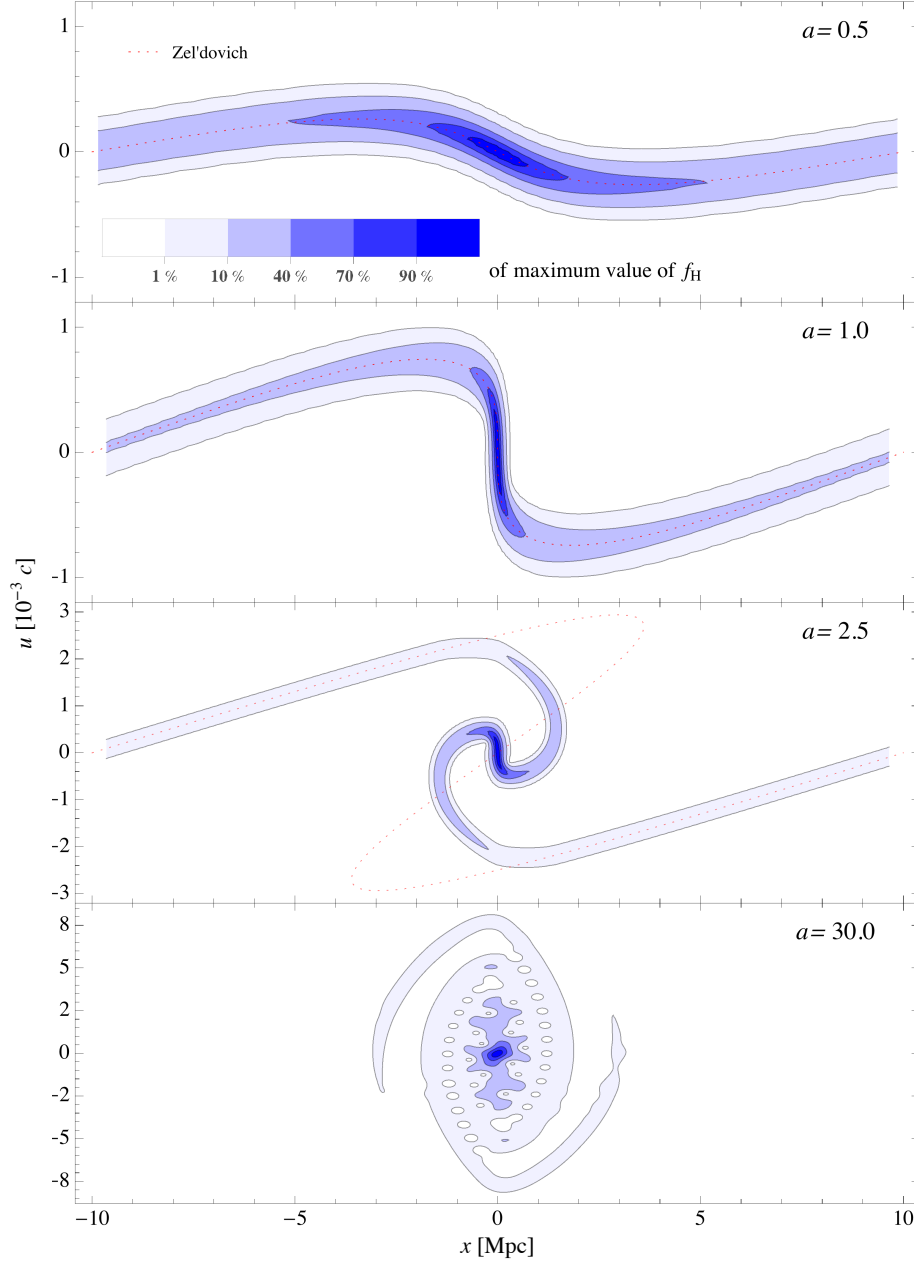

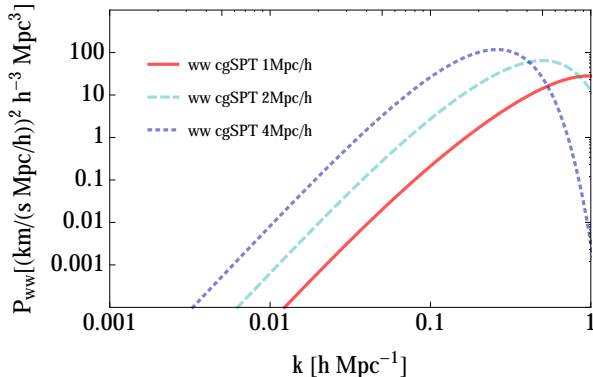

Figure 1. shaded Schrödinger method phase space density f_H , dotted exact dust solution.

3. Coarse-grained dust model

The coarse-grained dust model studied in [Uhlemann and Kopp, 2014] is limiting case of the Schrödinger method when $\hbar \rightarrow 0$ given by

$$\bar{f}_d(\mathbf{x}, \mathbf{p}) = \int \frac{d^3 x' d^3 p'}{(2\pi\sigma_x\sigma_p)^3} \exp \left[-\frac{(\mathbf{x} - \mathbf{x}')^2}{2\sigma_x^2} - \frac{(\mathbf{p} - \mathbf{p}')^2}{2\sigma_p^2} \right] f_d(\tilde{\mathbf{x}}, \tilde{\mathbf{p}}). \quad (3.1)$$

It is much closer to the distribution extracted from N-body simulations, which necessarily involves averaging over phase space cells of width σ_x and σ_p . Indeed, implementing the coarse-graining in this way results in a resummation in the large scale parameter of the macroscopic model suggested by [Dominguez, 2000] when the corresponding fluid-type equations are expressed in terms of coarse grained quantities.

The coarse-graining naturally leads to a mass-weighted velocity thereby generating large-scale vorticity which is also observed in N-body measurements [Hahn, Angulo and Abel, 2014] optimizing the agreement for a smoothing scale of $\sigma_x = 1$ Mpc.

Figure 2. Power spectrum of vorticity $\mathbf{w} = \nabla \times \mathbf{v}$ in 1-loop Eulerian perturbation theory for coarse-grained dust (cgSPT) and three different smoothing scales.

4. Prospects

Correlation functions of the phase space density are necessary for analyzing observations of large scale structure. Of particular interest is the 2-point correlation function in redshift space $1 + \xi(\mathbf{s}) = \langle (1 + \delta(\mathbf{s}_1))(1 + \delta(\mathbf{s}_2)) \rangle$ for biased tracers, like halos or galaxies, relevant to observations made in galaxy surveys. This is investigated for the coarse-grained dust model in [Kopp and Uhlemann et al., 2014].

The universality of halo density profiles may be understood by determining stationary complex solutions of the Schrödinger-Poisson equation. Since the Schrödinger method allows for virialization, it could prove useful in further analytical understanding of violent relaxation [Lynden-Bell, 1967] that leads to universal density profiles [Navarro, Frenk and White, 1997]. These properties might be derived from an entropy principle for collisionless self-gravitating systems as described in [He, 2012].
